Abstract

In CP violation measurements in asymmetric B-factory experiments, a determination of the B flavor of the neutral B mesons is necessary. A new method to this purpose using only three vectors of charged particles has been developed. This method (weighted charge method) does not require either lepton identification or charged-kaon identification. The tagging efficiency, probability for incorrect tagging, and effective tagging efficiency of this method are 43.1, 18.3, and 17.3%, respectively.

Asymmetric B-factories are being constructed to measure CP violation parameters in the B system[1, 2]. In such measurements, for example, $B^0(\bar{B}^0) \rightarrow \psi K_s$ decay must be identified by a full reconstruction. One should thus identify the B flavor of the other $B^0(\bar{B}^0)$ meson [$B^0(\bar{B}^0)$ -tagging] in order to determine the CP eigenstate at its decay timing. Hereafter, the description of B^0 includes its charge conjugation, i.e., $\bar{B}^0$. The typical methods of B^0 -tagging are lepton and charged-kaon tagging[3]. The effective tagging efficiency is written as

$$\epsilon_{eff} = \epsilon(1 - 2w)^2,$$

where ϵ and w are tagging efficiency and the probability for incorrect tagging, respectively. A typical value is $\epsilon_{eff}=0.28$ [1]. However, these methods require expensive devices, such as a CsI calorimeter and a ring imaging Čerenkov detector (RICH) [4]. Moreover, the performance of the RICH is still unknown, for example regarding the quantum efficiencies of the CsI photocathodes[5]. In this report, a new method (weighted charge method) which does not require either lepton or charged-kaon identification is introduced.

The dominant decay topology of the B^0 meson is back-to-back $(W) \rightarrow q\bar{q}, l\bar{l}$ and charm jets, where (W) is an intermediate W boson. Charm jets are also back-to-back (W) and strange jets in the center of the mass frame of the charmed particle. There is therefore a high probability that the charge state of the highest-momentum particle represents the B flavor of the parent B meson. Also, the kaon from the D meson may have a higher momentum because the D meson is boosted.

The present work began from highest-momentum particle tagging. The detector geometry assumed in this study is similar to that of the KEK B-factory experiment[1]. The beam energies were assumed to be 3.5 and 8 GeV. The detector covers polar-angle (θ) regions between 17 and 150 degrees. For a B -decay generator, JETSET6.3 was used[6]. A B^0 meson was generated along the beam-axis (zero polar

angle) with an energy of 5.75 GeV. This is because in the case of $B^0 \rightarrow \psi K_s$ decays, particles from this B^0 meson can be totally removed from the track sample. Also, the four-vector of the B^0 meson is exactly known at this point. Then, cuts at the polar-angle coverage and for $P_T > 0.15$ GeV were subjected to the decay products of the B^0 . The energies of all the charged particles were calculated assuming that they were charged pions. Finally, they were boosted to the CMS frame of this B^0 meson. In this method, ϵ is 100% by definition, because there is always a highest-momentum particle. A w was obtained to be 33%. Thus, ϵ_{eff} of 12% was obtained. This value is comparable to that of lepton-tagging.

In order to determine the other signatures, such as the D -decay topologies, a neural-network program (JETNET1.1) was used[7]. The input parameters were the four highest three-vectors and their charges. One middle layer with ten parameters was assumed. This program (neural network) calculates a quantity (we simply call it “output”) which is related to the B flavor, i.e., output=0 means B=-1 and output=1 means B=+1. A cut was applied on this quantity in order to determine the B flavor. The output of the neural-network is shown in Figure 1. The solid histogram is that for B^0 and the dashed is that for $\bar{B}^0$. The cut dependences on ϵ , w , and ϵ_{eff} are shown in Figure 2 by the solid, dashed, and dotted histograms, respectively. If cuts were made at 0.69 and 0.31 for B^0 and $\bar{B}^0$, respectively, ϵ and w of 43.1 and 18.3% were obtained, respectively. Thus, ϵ_{eff} was obtained to be 17.3%. This value is half that in the case of lepton and charged-kaon tagging. Hereafter, $\overline{cut}$ is used for the cut value of the neural-network output for $\bar{B}^0$.

So far we assumed perfect momentum resolution. The momentum resolution dependence was studied. Here, a resolution of

$$\delta P_T / P_T = \sqrt{0.005^2 + (0.005 P_T)^2}$$

was assumed. ϵ , w , and ϵ_{eff} of 43.2, 18.2, and 17.5% at $\overline{cut}=0.31$ were obtained. Therefore, no deterioration due to the momentum resolution was observed.

Since the decay-mode table of charmed particles in JETSET6.3 is not perfect, the decay-mode dependence should be verified. For this, JETSET7.3 was used[8]. An ϵ_{eff} of 17.4% with $\epsilon=47.8\%$ and $w=19.9\%$ was obtained at a similar $\overline{cut}$ level of 0.35. The ambiguity due to the decay modes of the charmed particles was ensured to be small. In the following studies, JETSET6.3 was used for this reason.

Figure 2: Cut dependences of ϵ , w , and ϵ_{eff} . The description of “cut” is described in the text. The solid histogram is for ϵ , the dashed for w , and the dotted for ϵ_{eff} .

Considering realistic conditions of B-factory experiments, lepton identification at $P^* > 1.4$ GeV was assumed to be perfect, where P^* is the lepton momentum in the B^0 rest frame. In Reference [3], the lepton tagging efficiency is 14% with 6% for incorrect tagging. In the KEK B-factory letter of intent [1], the lepton tagging efficiency is 10.6% with 4% for incorrect tagging. In our simulation, the lepton identification probability was assumed to be 100%. Then, an ϵ of 12.1% with $w=3.3\%$ was obtained, assuming the above P^* cut.

In addition, charged-kaon tagging was considered. There are two options for an asymmetric B-factory, i.e. (a) with and (b) without the RICH. For case (a), the identification of the kaon was assumed to be perfect at $P < 3.5$ GeV; for case (b), $P < 1.0$ GeV. Also, a special case (c) was added, i.e., a no-kaon identification option. This option is for a poor-man’s hadron B-factory[9]. For case (a), ϵ and w were obtained to be 39.2 and 8.5% and for case (b), they were 30.4 and 10.6%, respectively. Using both lepton and charged-kaon tagging and considering their overlap, ϵ_{eff} ’s of 34.0 and 26.6% were obtained for cases (a) and (b), respectively.

The results of the weighted charge method were as follows. The events tagged by either the lepton or the charged-kaon were removed from the samples. Thus, the efficiencies mentioned hereafter were re-defined considering a reduction of an event portion by the lepton and/or charged kaon taggings. The results are summarized in Table 1. Case (d) in Table 1 is that without either lepton or charged kaon identification for comparison with case (a)-(c). The outputs of the neural-network studies are shown in Figures 3 (a), (b), and (c) for the three cases described so far, respectively. In case (c), a hadron collider B-factory without a RICH was assumed. In this case, if the B^0 vertices are well identified, only charged tracks from the B^0 can be selected. The exact four-vector of the B^0 was unknown, however for simplicity, the four-vector is assumed to be known exactly.

In case (a), the improvement was only 10% as seen in Table 1. However, in cases (b) and (c), significant improvements were observed. In case (b), the RICH performance was almost recovered. In case (c), the performance of the weighted charge method was close to half that of the case of perfect kaon identification. In a practical case, the four-vector of B^0 is unknown. One must therefore use the transverse momentum with respect to the B^0 -jet axis instead of three-vectors at the CMS frame. This will decrease the performance of this tagging.

Figure 3: Output distributions of the neural-network studies: (a), (b), and (c) correspond to the cases described in the text. The horizontal axis is the output of the neural network and the vertical is the number of events. The solid histograms are for B^0 and the dashed $\overline{B}^0$.

lepton and kaon tags				
Case	lepton-ID P^* cut	kaon-ID P cut	ϵ_{eff}^0	
(a)	1.4 GeV	3.5 GeV	33.7	
(b)	1.4 GeV	1.0 GeV	26.5	
(c)	1.4 GeV	none	10.4	
(d)	none	none	0	
this method				
Case	ϵ	w	ϵ_{eff}	ϵ_{eff}^{tot}
(a)	18.1	29.2	3.12	36.8
(b)	24.4	24.3	6.42	32.9
(c)	43.2	27.1	9.03	19.4
(d)	43.1	18.3	17.3	17.3

Table 1: Percentages of ϵ , w , and ϵ_{eff} for four cases described in the text. Here, the efficiencies were renormalized by excluding the lepton-kaon tagging events as described in the text. Also shown are the effective tagging efficiencies for the lepton-kaon tagging (ϵ_{eff}^0) and total effective tagging efficiencies, i.e., $\epsilon_{eff}^{tot} = \epsilon_{eff}^0 + \epsilon_{eff}$, respectively.

As can be seen from Figures 3 (a), (b), and (c), the peaks at around 0.1 and 0.9 are considered to be those for prompt particles. The broad structures at around 0.35 and 0.65 are considered to be other contributions such as high-momentum kaons.

In a real experiment, there are two ways to tune the cut parameters. One is to tune them by a Monte-Carlo simulation, and the other to obtain ϵ_{eff} using more than 1000 fully reconstructed B^0 events. Here, a fully-reconstructed B^0 event means an event where one of the B^0 's is reconstructed exclusively. There, however, is an ambiguity in the $B^0 - \bar{B}^0$ oscillation in the determination of the B flavor of the other B^0 . The other method is to obtain more than 10000 fully reconstructed events for tuning in order to avoid fragmentation model ambiguities. Also, at a B-factory, one expects $> 1 \times 10^7$ $B^0 \bar{B}^0$ events per year. Therefore, the B^0 reconstruction efficiency of 0.1% will give 20000 reconstructed events. Both methods are considered to be valid.

In order to establish this method, the B^0 decay-mode studies at CLEO are important. This method strongly relies on the fragmentation model of $(W) \rightarrow q\bar{q} \rightarrow \text{hadrons}$. Also, a theoretical consideration concerning this nature would be of great benefit.

In the neural-network studies, the simplest parametrization was used, i.e., three-vectors and the charges of the four highest-momentum particles. It may be more effective if a new parametrization is found. For example in B-factory cases, neutral particles can be used for jet identifications.

To conclude, a new method to identify the B flavor of B^0 mesons in a CP violation measurement at the asymmetric B-factory was developed. This method does not require either lepton or charged-kaon identification. The tagging efficiency, probability for incorrect tagging, and effective tagging efficiency were obtained to be 43.1, 18.3, and 17.3%, respectively. This effective tagging efficiency is significantly large compared with that of lepton tagging. In the case with charged-kaon tagging, however, the gain is small. This method will be helpful especially at an initial stage of the B-factory where such particle identification devices as RICH cannot be fully operated.

I appreciate discussions with members of the BELLE collaboration.
